THE PERFORMANCE OF INDEX BASED LIVESTOCK INSURANCE: EX ANTE ASSESSMENT IN THE PRESENCE OF A POVERTY TRAP

Abstract

Index-based livestock insurance (IBLI) is designed to compensate vulnerable pastoralists for area average predicted livestock mortality loss in northern Kenya, where previous work has established the presence of poverty traps. This paper conducts initial, ex-ante evaluation of the effectiveness of this new insurance product, scheduled for commercial pilot in early 2010, given the tradeoff between its advantages in reducing transaction costs and asymmetric information problems and the presence of basis risk resulted from imperfect correlation between the insurance coverage and individuals’ loss experience. We simulate household-specific wealth dynamics based on a dynamic model parameterized using rich panel and experimental data from the region. The simulations allow us to establish the welfare effects of and to investigate patterns of willingness to pay for this asset index insurance. We show that the bifurcated livestock dynamics associated with the poverty trap gives rise to insurance valuation that is highly nonlinear in individual herd size. Willingness to pay among vulnerable groups who most need insurance are, on average, lower than commercially viable rates. And some schemes of targeted subsidization of IBLI premiums appear to offer more cost-effective poverty reduction than direct need-based transfers to the poor.

Keywords: Index insurance, asset risk, bifurcated wealth dynamics, nonlinear growth, poverty traps, safety net, risk preference elicitation, livestock system, pastoralists, Kenya

1. Introduction

Recent theoretical and empirical evidence suggests various mechanisms by which uninsured – especially covariate climate or natural disaster – risks play in perpetuating extreme rural poverty in developing countries. The combination of considerable ex-post, observable asset or income losses due to catastrophic shocks (Dercon 2005, Dercon and Hoddinott 2005, Krishna 2006, Hoddinott 2006), and the likewise substantial, albeit less obvious opportunity costs of ineffective ex-ante risk management (Eswaran and Kotwal 1989, 1990, Rosenzweig andBinswanger 1993, Zimmerman and Carter 2003) are shown to directly condition household’s asset accumulation and their long-term livelihood dynamics in the presence of a threshold-based poverty trap characterized by multiple equilibria of well being and at least one critical wealth threshold, below which household’s livelihood commonly fall into low-level poverty equilibrium.
Effective risk management mechanism that protects households against losses that cast them catastrophically below that critical threshold thus can yield handsome payoff of higher economic growth and lower long-run poverty rates (Alderman and Haque 2007, Carter and Barrett 2006). In the rural vulnerable communities, however, existing informal risk management mechanisms as well as conventional insurance market often fail due to the classic incentive problems, high transaction costs and covariate nature of catastrophic risks. Hence burgeoning interest in the new insurance instruments as a means of overcoming poverty traps (Barnett, Barrett and Skees 2008, Barrett et al. 2008).

Index insurance has gained widespread interest in recent years as an instrument for reducing uninsured risk in poor rural areas that typically lack access to commercial insurance products. These financial instruments make indemnity payments based on realizations of an underlying index – based on some objectively measured random variable – relative to a pre-specified threshold, the “strike” (Barnett et al. 2008). Index insurance offers significant potential advantages over traditional insurance. Because indemnity payments are not based on individual claims, insurance companies and insured clients need only monitor the index to know when payments are due. This sharply reduces the transaction costs of monitoring and verifying losses, while also eliminating the asymmetric information problems (i.e., adverse selection and moral hazard) that bedevil conventional insurance. These advantages have sparked considerable interest in index insurance for poor regions otherwise lacking formal insurance access (Barnett and Mahul 2007).

The advantages presented by index insurance with reduced transaction costs and asymmetric information problems, however, come at the cost of increased “basis risk”, the imperfect correlation between an insured’s loss experience and the behavior of the underlying index on which the index insurance contract is written. A contract holder may experience losses but not receive a payout if the overall index is not triggered. Conversely, the aggregate experience may trigger indemnity payments even to insurees who experience no loss.

Given the tradeoff between basis risk and reduced incentive problems and transactions costs, the impact of index insurance on well-being remains unknown, especially in the case of index insurance on assets that determine the time path of future earnings and welfare. And because index insurance is so new, with limited uptake and predictable questions about the quality of the initial contracts, there is no empirical evidence yet as to the impact of index insurance on the well-being of otherwise-uninsured poor populations. This paper offers some initial, ex ante impact assessment findings related to a specific index insurance contract that is scheduled for commercial launch in January 2010 in one of the world’s most infrastructure-deficit and vulnerable regions. It also offers an innovative approach to establishing the welfare effects of and willingness to pay for asset insurance and demonstrates how the presence of asset thresholds associated with poverty traps can affect insurance valuation and performance.

The arid and semi-arid lands (ASAL) of east Africa are among the poorest regions on Earth, with severe (less than $1/day) poverty rates routinely in excess of 75%. Given meager rainfall and infrastructure, the pastoralist populations who inhabit these areas rely heavily on extensive livestock grazing for their livelihood. Recent economic research, building on extensive prior ethnographic work, finds that east African pastoralists operate
in an environment characterized by multiple herd size equilibria characteristic of poverty traps (Lybbert et al. 2004, Barrett et al. 2006). The prominent role that covariate climate risk plays in driving pastoral poverty traps (Santos and Barrett 2007) and growing concern that droughts are driving growing numbers of pastoralists into destitution (Sandford 2006, Little et al. 2008), naturally motivated the recent development of index-based livestock insurance (IBLI) against catastrophic herd loss in the northern Kenyan ASAL (Chantarat et al. 2009a). These IBLI products are being commercially piloted beginning in January 2010.

Like typical insurance, IBLI compensates for livestock loss. But unlike traditional insurance, it only compensates for covariate herd losses that are predicted by the historical relationship with remotely sensed Normalized Differential Vegetation Index (NDVI) measures; an indicator of vegetative cover widely used in drought monitoring programs in Africa. These data are publicly available in near-real time and objectively verifiable. Chantarat et al. (2009a) explain the details of the IBLI contract design and show that it performs extremely well out-of-sample in insuring against catastrophic covariate shocks in this region. In this paper we use household-level panel data to simulate the impact of IBLI on Northern Kenyan pastoral households’ welfare dynamics.

This paper makes several novel contributions to the literature. First, IBLI insures assets rather than income. Although the overwhelming majority of the global insurance market insures assets through property and casualty, life or health insurance products, most index insurance on offer in the developing world focus on replacing lost income, typically due to rainfall shocks that affect crop production. The loss of productive assets like livestock potentially disrupts future income processes, not just current earnings. Furthermore, in the presence of a poverty trap, shocks that push herd sizes below a critical threshold at which herd dynamics bifurcate can have especially severe consequences. The point of bifurcation is critical because below this threshold the rate at which the livestock asset is depleted due to death loss far exceeds any short run possibility of rejuvenating the herd. Thus insurance that effectively protects households from slipping into the poverty trap can be of especially high value. Conversely, insurance that consumes scarce resources and fails to protect the household from catastrophic shocks can do damage. Given these considerations, we evaluate IBLI’s performance using a dynamic model rather than the usual static approach employed in the existing literature. We show that the effectiveness of IBLI depends on initial herd size relative to the bifurcation threshold as well as, to a lesser degree, on household-specific basis risk and risk preferences.

Second, rather than modeling performance for a representative agent, as is the norm in the extant literature (Skees et al. 2001, Turvey and Nayak 2003, Vedenov and Barnett 2004, Deng 2007 and Carter et al. 2007), we explicitly study how IBLI performance varies based on variation in household characteristics, such as initial herd size, and key basis risk and risk preference parameters. And rather than making assumptions about these parameters, we estimate them from panel data and field experiments from the targeted area. Contracts that perform well for a representative household may not prove effective for the majority nor for target sub-populations. We show that to be the case with IBLI.
Third and finally, household-level simulation analysis allows us to compare the outcomes of various subsidization programs and targeting schemes. Our analysis finds that IBLI subsidies targeted toward vulnerable-but-non-poor pastoralists create an effective safety net by protecting such households from slipping into a poverty trap after a drought. This reinforces prior work suggesting that safety net interventions targeting the non-poor can reduce poverty in the long run by stemming the rate of inflow into the ranks of the chronically poor following a shock (Barrett et al. 2008).

The rest of the paper is organized as follows. Section 2 briefly explains the study locations and the data. Section 3 introduces IBLI. Section 4 then describes the dynamic model we use in the simulations and introduces the certainty equivalent herd growth rate, which we use as a key performance evaluation criterion. Section 5 estimates distributions of basis risk, risk preferences and other key household characteristics necessary for the simulations. Section 6 reports the estimated IBLI performance and how this varies based on identifiable household characteristics. Section 7 estimates households’ willingness to pay for the optimal contract and district-level aggregate demand for IBLI. Section 8 then explores how alternative approaches to offering IBLI commercially or with safety net subsidies affect wealth and poverty dynamics in the system. Section 9 concludes.

2. The Study Area and Data
Extensive livestock grazing represents the key livelihood in the northern Kenyan ASAL. Pastoralists move their herds in response to spatiotemporal variability in forage and water access. Northern Kenya experiences bimodal rainfall, defined by long rains that fall March-May, followed by a long dry season (June-September) season, then a short rains season from October-December followed by a January-February short dry season. We henceforth refer to the March-September period as the LRLD season (for long rains and long dry), and the October-February period as SRSD (for short rains and short dry). When the rains fail, especially over two rainy seasons in a row, catastrophic herd losses commonly ensue.

We investigate IBLI performance in Marsabit District, Kenya, for which this product was developed on a pilot basis. We use data from four locations – Dirib Gombo, Logologo, Kargi and North Horr (Figure 1) – from which we have two complementary household-level data sets: panel data collected quarterly from 2000-2002 on around 30 households in each location by the USAID Global Livestock Collaborative Research Support Program “Improving Pastoral Risk Management on East African Rangelands” (PARIMA) project (Barrett et al. 2008), and a separate survey fielded during May-August 2008 among 42 households in each location (Chantarat et al. 2009c). The latter survey included field experiments to elicit risk preferences.

Table 1 summarizes key characteristics of the four study locations. Dirib Gombo, on Mount Marsabit, enjoys relatively higher rainfall and is occupied mostly by cattle- and smallstock-keeping Boran pastoralists who also rely on town-based livelihood opportunities to complement their meager livestock holdings. Logologo is along the main road, with a relatively more arid climate and larger cattle and smallstock herds based on

---

1 All summary statistics are weighted by appropriate stratified sampling weights.
transhumant pastoralism. Kargi and North Horr are very arid locations on opposite edges of the Chalbi desert, where camel- and smallstock-keeping pastoralists rely on longer distance migrations to cope with greater spatiotemporal variability in forage and water availability.

Sample households rely on livestock and livestock products for 18-87% of their income. Severe poverty is widespread and inversely correlated with herd sizes because livestock are the main productive asset owned in the region. As a result, livestock mortality is considered the main threat to pastoralists’ livelihood. Households’ seasonal livestock loss 2000-2002 (including a bad drought in 2000) ranged from the lowest average seasonal rate of 7% in North Horr to a high of 21% in Dirib Gombo. The long-term consequence of the 2000 catastrophic drought can be seen in the drastic reduction in overall mean herd size from 25 TLU at the beginning of 2000 to 15 TLU at the end of 2008. Extreme (>20%) herd losses occurred in roughly 20% (10-15%) of seasons in Dirib Gombo and Logologo (Kargi and North Horr). These catastrophic losses were typically due to covariate shocks related to forage and water availability, while modest losses of individual animals were more commonly idiosyncratic experiences (e.g., due to predators or injury).

3. Index Based Livestock Insurance

Chantararat et al. (2009a) use a large, repeated cross-sectional household data set collected by the Kenyan government at monthly frequency, 2000-2008, to establish a strong predictive relationship between area average herd mortality rates and the satellite-based, remotely sensed vegetation index series, the normalized difference vegetation index for different locations \( l \) and seasons \( t \) \((\text{ndvi}_l^t)\). The resulting predicted livestock mortality rate, \( \hat{M}(\text{ndvi}_l^t) \), thus serves as the index triggering IBLI indemnity payments for that particular location relative to a pre-specified “strike” level, \( M^* \). The IBLI contract \( (\hat{M}^*, \hat{M}(\text{ndvi}_l^t)) \) makes indemnity payments \( \pi_h(\hat{M}^*, \hat{M}(\text{ndvi}_l^t)) \) equal to the increment of predicted losses \( \hat{M}(\text{ndvi}_l^t) \) beyond the strike \( M^* \), expressed as a percentage of the insured herd value as

\[
\pi_h(M^*, \hat{M}(\text{ndvi}_l^t)) = \max(\hat{M}(\text{ndvi}_l^t) - M^*, 0).
\]

The location-specific actuarially fair premium rate of IBLI, at which the insurer will break even in the long run, thus equals to area averaged indemnity payment rate of the particular location, and thus can be estimated based on the empirical distribution of NDVI of the particular location. For IBLI to be commercially viable, the insurance underwriter also adds other costs covering, e.g., administration, model uncertainty and require profit margins, in the form of premium loading \( a \geq 0 \) over the actuarially fair
rate. The loaded premium rate for location \( l \), quoted as a percentage of total insured herd value, can therefore be calculated as

\[
\rho_i^l \left( M^*, \hat{M} (ndvi_{lt}) \right) = (1 + a) E \pi_{lt} = (1 + a) \int \text{Max} \left( \hat{M} (ndvi_{lt}) - M^*, 0 \right) f(ndvi_{lt}).
\]

The left panel of Table 2 summarizes the predicted mortality index \( \hat{M} (ndvi_{lt}) \) for each of the four study locations constructed using the full NDVI series available from 1982-2008 and the livestock mortality forecasting model developed by Chantararat et al. (2009a). The predicted herd mortality indices average 8-9%. The right panel of Table 2 also shows the actuarially fair IBLI premium rate, which varies across locations due to differences in the distributions of predicted herd mortality index. In what follows, we use 54 seasons of predicted area average herd mortality and the associated fair premium rates to evaluate IBLI performance.

4. **Analytical Framework**

With this simple background on the region, the data and IBLI behind us, we now develop a simple dynamic model that accommodates the nonlinear, bifurcated herd dynamics previously observed in the region, with a critical herd size threshold typically in the range of 10-20 tropical livestock units (TLU)\(^3\) (Lybbert et al. 2004, McPeak 2004, Barrett et al. 2006, Santos and Barrett 2007). This model generates multiple welfare equilibria, the lowest of which is associated with a poverty trap. As will be clear, the presence of the threshold affects the valuation of IBLI conditional on a household’s current herd size.

4.1 **A Stylized Model of Bifurcated Livestock Dynamics**

Denote the herd size, in TLU, realized by household \( i \) in location \( l \) at the beginning of season \( t \) (and so at the end of season \( t-1 \), where seasons alternate within a year between LRLD and SRSD) as \( H_{lt} \). Herd dynamics are governed by various stochastic processes: the rate of biological reproduction, denoted by \( \tilde{h}_{lt} \), the gross non-biological herd recruitment rate, \( \tilde{r}_{lt} \) (which includes purchases, borrowed animals, transfers in, etc.), the gross herd offtake rate, \( \tilde{o}_{lt} \) (which includes slaughters, sales, transfers out, etc.) and the herd mortality rate, \( \tilde{M}_{lt} \). Pastoralists face a subsistence constraint that can be summarized as a required seasonal livestock offtake level, \( H^c \), that covers the minimum consumption required for every household member. In this model, we assume households have identical membership structures and thus \( H^c \) is the same for each household.

---

\(^{2}\) The average premium loading for agricultural insurance contracts is in the range of 30-50%. See, for example, the USDA Risk Management Agency’s or the Farmdoc’s Premium Estimator for available insurance policies for several states and important grain crops in the U.S. (http://www.rma.usda.gov/policies/2006policy.html ; http://www.farmdoc.uiuc.edu/cropins/index.html).

\(^{3}\) 1 TLU = 1 cattle = 10 goats or sheep = 0.7 camels.
The stochastic herd reproduction, mortality and herd offtake and recruitment decisions depend on the risks inherent in the system. The main covariate component in household asset risk is related to rangeland conditions, and so is characterized by the vegetation index \( \text{ndvi}_t \) that follows location-specific probability distribution \( f(\text{ndvi}_t) \).

Each household also faces other sources of risk, \( e_i \), drawn from probability distribution \( h(e_i) \), that are uncorrelated with the covariate component explained by vegetation index. This latter component includes mainly idiosyncratic shocks experienced by specific households – such as conflict, raiding, predation, accidents, etc. – as well as other covariate risk unrelated to range conditions – such as disease outbreaks – although we find the latter is relatively small compared to the covariate component. Together these processes generate the net stochastic herd growth rate in period \( t \), which nets out herd offtake and mortality rates from the reproduction and herd recruitment rates so that the seasonal herd accumulation can be characterized by

\[
H_{it+1} = \left( 1 + \tilde{b}_{it}(\text{ndvi}_i, e_{it}) + \tilde{i}_{it}(\text{ndvi}_i, e_{it}, H_{it}) - \max\left\{ \tilde{o}_{it}(\text{ndvi}_i, e_{it}, H_{it}), H^c \right\} - \tilde{M}_{it}(\text{ndvi}_i, e_{it}) \right) H_{it}
\]

where the stochastic herd size \( H_{it+1} \) is realized at the end of period \( t \). The net offtake rates vary with a household’s beginning herd size, \( H_{it} \), which implicitly determines role of livestock in the household and so their livestock transaction decisions. We, however, abstract here from modeling each of these livestock transaction choices; instead we simply calibrate this growth function based on the observed household longitudinal data.

The stochastic net growth function (e.g., \( \tilde{b}_{it} + \tilde{i}_{it} - \tilde{o}_{it} - \tilde{M}_{it} \)) defined in equation (3) is assumed to be continuous, equal to zero when the beginning herd size is zero and bounded from below at zero. Equation (3) thus implies nonlinearities in herd accumulation, at least, due to the consumption requirement, \( H^c \), which imposes a regressive fixed cost rate – inversely proportional to the beginning herd size – on the rate of return on livestock asset. Given the fixed subsistence consumption requirement, households with smaller herd sizes must consume a larger portion of their herd. Herd decumulation results where net herd growth falls below the minimum consumption rate.

The resulting nonlinearity in net herd growth implies a bifurcation in herd accumulation characterized by at least one (subsistence-driven) threshold \( H^*(H^c) \) above which herd size is expected to evolve toward a high-level equilibrium and below which it is expected to fall to a poverty trap equilibrium. Equation (3) can therefore be rewritten as a nonlinear net herd growth function \( \eta(\cdot) \) such that the expected net herd growth conditional on herd size bifurcates at the critical herd threshold \( H^*(H^c) \):

\[
H_{it+1} = \eta(\text{ndvi}_i, e_{it}, H_{it}) \quad \text{where} \quad E\eta'_{it}(\cdot) < 0 \quad \text{if} \quad H_{it} < H^*(H^c)
\]

\[
E\eta'_{it}(\cdot) \geq 0 \quad \text{if} \quad H_{it} \geq H^*(H^c).
\]

7
At a reasonable, ground trusting level of subsistence consumption at 0.5 TLU per season per household, Figure 2 illustrates the nonlinear expected net herd growth estimated nonparametrically using observed household herd data (birth, mortality, purchase, exchange, sale, slaughter and transfer rates) in 2000-2002 and 2007-2008. This pattern implies the bifurcated herd threshold at around 15 TLU per household – consistent with previous findings (Lybbert et al. 2004, McPeak 2004, Barrett et al. 2006, Santos and Barrett 2007) – below which herds collapse over time toward a stable equilibrium of 0 TLU, implying an exit from pastoralism. Above that threshold, herds grow toward a high level stable equilibrium size of 55-60 TLU.

Household \( i \) derives intertemporal utility based on a simplified Constant Relative Risk Aversion (CRRA) function defined over livestock wealth as

\[
U(H_{it}, \tilde{H}_{it+1}(H_{it}), ..., \tilde{H}_{it+T}(H_{it}), ...) = E_t \left( \sum_{t=0}^{\infty} \delta^{t-t} u(H_{it}) \right)
\]

where

\[
u(H_{it}) = \frac{\tilde{H}_{it}^{1-R_i}}{1-R_i}
\]

\(0 < R_i \leq 1\) is the Arrow-Pratt coefficient of relative risk aversion and \(\delta \in (0,1)\) is the discount factor. In order to make the implications of risk aversion more transparent, certainty equivalent herd growth rate is used to express household’s valuation of their stochastic herd dynamics. In particular, a certainty equivalent herd growth rate for any herd dynamics is defined as the constant net herd growth rate with respect to the initial herd, \(H_{it}\), (thus yielding stabilized herd size over time) that yields the same level of well-being as the expected intertemporal utility obtained from the stochastic herd dynamics. The certainty equivalent growth rate, \(\eta^t\), of the stochastic herd dynamics, \(\{\tilde{H}_{it}^t\}_{t=0}^{T}\), is thus implicitly defined by the following equation

\[
u(H_{it}) = \frac{\tilde{H}_{it}^{1-R_i}}{1-R_i}
\]

\[
U(\eta^t_i H_{it}, ..., \eta^t_i H_{it}) = E_t U(\tilde{H}_{it+1}(H_{it}), ..., \tilde{H}_{it+T}(H_{it}), ...).
\]

Because of the direct link between herd and consumption or livelihood dynamics, this certainty equivalent growth rate also provides a direct household welfare measure. Using (6), IBLI increases household welfare if it increases the certainty equivalent herd growth rate relative to that of the uninsured herd dynamics. Therefore, an improvement in certainty equivalent growth rate, \(\Delta \eta^t_i = \eta^{c_i}_i - \eta^{c_n}_i\), representing additional risk premium

\[\begin{align*}
\text{Previous survey work in this region finds average livestock offtake for household consumption averages slightly less than one goat a month (McPeak 2004). According to FAO (1992), five goats (each yielding 20 kilograms of meat equivalent to 5000 grams of protein) gives an average family of three 46 grams of protein per day per individual, nearly the recommended daily intake of 50 grams of protein per day per individual.} \\
\text{The function is estimated using Epanechnikov kernel with rule-of-thumb optimal bandwidth.} \\
\text{If } \delta = 1, \text{ this can be written more generally as } U(\eta^{c_i}_i H_{it}) = EU(\tilde{H}_{it+1}^t (H_{it})).
\end{align*}\]
in term of growth rate that a household is willing to sacrifice for IBLI, thus provides a measure of dynamic welfare improvement due to insurance. This measure has general applicability to dynamic welfare analysis with respect to any asset insurance.

The certainty equivalent growth rate thereby provides a convenient measure of the intertemporal welfare impact of IBLI given the underlying herd dynamics, in contrast to the existing literature, which concentrates on static impact analysis. This is important because IBLI performance in the initial insured seasons affects performance in later seasons through the reinforcing impact of herd dynamics where growth patterns are nonlinear, as in this setting. For example, if IBLI fails to protect household from losses in the initial seasons that set it on the herd decumulation trajectory, IBLI’s long-term performance could be compromised by the initial herd collapse and ensuing dominant herd dynamics. Because the welfare and growth effects of loss vary depending on where in the herd size distribution one experiences loss, standard insurance performance measures based on induced changes in outcome distributions will not suffice in this setting.

4.2 Managing Mortality Risk with IBLI

IBLI compensates for covariate livestock mortality loss based on the predicted herd mortality index in each location, \( \hat{M}(ndvi_h) \). For simplicity, we assume that the household insures either all or none of their herd at the start of each season, which enables us to compare fully insured herds under several contract specifications against the case of no insurance. The insured herd size realized at the end of coverage season \( t \) for a household in location \( l \) can thus be written as

\[
(7) \quad \tilde{H}_{ilt+1} = (1 + \tilde{g}_{ilt}(ndvi_h, e_{ilt}, H_{ilt} | H^c) - \tilde{M}_{ilt}(ndvi_h, e_{ilt}) + \pi_{ilt} - \rho_t^c) \cdot H_{ilt}
\]

where \( \tilde{g}_{ilt} \) represents the non-mortality component in the net growth rate in (3).

IBLI thus reduces expected net herd growth in good seasons by the IBLI premium, \( \rho_t^c \), but it should at least partially compensate for losses during periods of substantial covariate herd mortality through the indemnity payment, \( \pi_{ilt} \). Given certain cost and uncertain benefit, the household-specific basis risk with respect to the contract \( (M', \hat{M}(ndvi_h)) \) is thus a key determinant of IBLI performance. According to (1) and (7), basis risk depends on the correlation between the predicted area average mortality index, \( \hat{M}(ndvi_h) \), and the individual-specific mortality rate, \( \tilde{M}_{ilt}(ndvi_h, e_{ilt}) \). The larger the proportion of predictable covariate loss in a household’s individual mortality loss, the greater the gains from IBLI.

---

7 Another approach concentrates on measuring changes in the distribution of the insured outcome based on mean-variance measures, e.g., coefficient of variation, value at risk and downside risk measures (Skees et al. 2001; Turvey and Nayak 2003; Vedenov and Barnett 2004). Since that approach ignores the insuree’s risk preferences, it may misestimate the benefit of insurance (Fishburn 1977; Breustedt et al. 2008).
Specifically, the relationship between household-specific and the area average predicted livestock mortality rates can be expressed by a beta representation form of the hedgable predicted mortality index as

\[ \tilde{M}_{il}(ndvi_{il}, \varepsilon_{ilt}) = \mu_{il} + \beta_{il} (\hat{M}(ndvi_{il}) - \hat{\mu}_l) + \varepsilon_{ilt} \tag{8} \]

where \( \mu_{il} \) reflects household \( i \)'s long-term average livestock mortality rate, which implicitly reflects household-specific characteristics that determine their livestock loss (e.g., herding ability); \( \hat{\mu}_l \) is the long-term mean of the predicted mortality index for location \( l \); \( \beta_{il} \) is household-specific parameter giving the average, or systematic relationship between the individual loss experience and the area average predicted rate, and \( \varepsilon_{ilt} \) reflects variations in livestock loss experience that are not correlated with the covariate component captured by the index.

The value of IBLI to an individual household hinges on the combination of the three distinct, interrelated household-specific basis-risk determinants, \( \{ \mu_{il}, \beta_{il}, \varepsilon_{ilt} \} \). The coefficient \( \beta_{il} \) measures the sensitivity of the household’s mortality experience to the predicted herd mortality index in its area. \( \beta_{il} = 1 \) represents the case in which deviations of household \( i \)'s livestock losses from its long-term average are, on average, perfectly explained by variations in the predicted area average mortality index. In contrast, \( \beta_{il} = 0 \) implies that there is no systematic relationship between the household’s livestock mortality loss and the area average predicted index. If the household-specific mean mortality \( \mu_{il} \) is relatively similar to the location-specific mean predicted mortality rate \( \hat{\mu}_l \), then the closer \( \beta_{il} \) is to one, the better will the predicted mortality index explain household’s losses, and so the lower the basis risk. Pastoralists with \( \beta_{il} \) lower (greater) than one or with \( \mu_{il} \) lower (greater) than \( \hat{\mu}_l \) therefore tend to over (under)- insure their herd mortality losses using IBLI. In addition to \( \beta_{il} \) and \( \mu_{il} \), which govern the expected relationship between the individual and area average predicted loss from vegetation index, the other unrelated risk that household faces in any given year, \( \varepsilon_{ilt} \), also reflect the relative proportion of household’s overall losses that are not manageable by IBLI. And so the greater its variance, the larger the basis risk.

Incorporating (8), our analytical framework thus implies that the risk management effectiveness of any IBLI contract \( \{ M^*, \hat{M}(ndvi_{il}), \rho_{il}^* \} \) can be appropriately measured by \( \Delta \eta^*_i = \eta(ndvi_{il}, \mu_{il}, \beta_{il}, \varepsilon_{ilt}, R_i, H_{ilt}) \). This emphasizes the standard theoretical result that exposure to location-specific covariate risk, household-specific basis risk parameters and

---

8 Miranda (1991), Mahul (1999) and Carter et al. (2007) also use variant of this specification.

9 Formally, \( \beta_{il} \) is equal to \( \text{cov}(\hat{M}_{ilt}, \hat{M}(ndvi_{il}))/\text{var}(\hat{M}(ndvi_{il})) \), the OLS coefficient in a regression of \( (\hat{M}_{ilt} - \mu_{il}) \) on \( (\hat{M}(ndvi_{il}) - \hat{\mu}_l) \).
risk preferences serve as key determinants for IBLI performance. A critical innovation with this approach is that the presence of a threshold-based poverty trap further implies that IBLI performance also depends on household herd size. This analytical framework serves as the basis for the estimation and simulation in Section 5.

4.3 Threshold-based IBLI Performance

In order to show analytically how IBLI valuation might deviate from the standard insurance evaluation in the presence of bifurcated asset dynamics, we simplify the model by discretizing the nonlinear net herd growth in (4) into an additive form:

\[ H_{it+1} = A(H_{it}) + \tilde{B}(ndvi_{it}, \varepsilon_{it}) \cdot H_{it} \]

with

\[ A(H_{it}) = \begin{cases} \eta_L H_{it} & \text{if } H_{it} < H^* \\ \eta_H H_{it} & \text{if } H_{it} \geq H^* \end{cases} \]

and

\[ \tilde{B}(ndvi_{it}, \varepsilon_{it}) = \begin{cases} \eta_g + \varepsilon_{it} & \text{with probability } P \\ \eta_B + \varepsilon_{it} & \text{with probability } 1 - P \end{cases} \]

where \( A(\cdot) \) represents the deterministic component of the herd growth rate, which is conditional on the initial herd size relative to the critical threshold with \( 0 < \eta_L < 1 \) and \( \eta_H > 1 \). The relation \( \tilde{B}(\cdot) \) is the stochastic component of herd growth written as the sum of the insurable covariate component captured by the vegetation index \( (\eta_g > 0) \) in a good vegetative season with probability \( P = \int_0^M \tilde{M}(ndvi_{it})d\tilde{f}(ndvi_{it}) \) and \( \eta_B < 0 \) in a bad season with probability \( (1 - P) \) and the uncovered component with \( E(\varepsilon_{it}) = 0 \).

Starting with a simplified scenario without stochastic disturbance on herd growth, \( \tilde{B}(ndvi_{it}, \varepsilon_{it}) \), we can simply derive recursively two stable intertemporal welfare levels:

\[ U(H_{it}, A(H_{it}), A(H_{it+1}), \ldots) = \frac{u(H_{it})}{1 - \delta \eta_i^{1-n_i}} \]

where \( \eta_i = \begin{cases} \eta_L & \text{if } H_{it} < H^* \\ \eta_H & \text{if } H_{it} \geq H^* \end{cases} \)

with \( 0 < \eta_L < 1 \) eventually leading those with \( H_{it} < H^* \) into the poverty trap, a long-run equilibrium herd size close to zero.

We now consider the expected impact of IBLI in a scenario when household is exposed to the stochastic component of herd growth in the current season \( t \) that will condition herd accumulation toward the next season. By paying premium rate of \( \rho_{it} \) per total insured livestock value at the beginning of the season, they can acquire an insurance coverage for the covariate shock explained by the vegetation index in the current season, which pays \( \pi_{it} \) per value of insured livestock at the end of the season if the season turns...
out to be a bad vegetative season with probability $1 - P$ and pays nothing if it is a good season with probability $P$. Household $i$'s certainty equivalent herd growth rate with respect to their uninsured herd dynamics with exposure of stochastic risk in period $t$ without insurance implicitly derived from:

\[
U(\eta_i^t, H_{it}, \ldots) = E_i U\left(A(H_{it}) + \tilde{B}(ndvi_{it}, \varepsilon_{it})H_{it}, A(H_{it}) + \tilde{B}(ndvi_{it}, \varepsilon_{it})H_{it}, A(H_{it+1}), \ldots\right)
\]

thus depends on the realization of stochastic herd growth relative to the initial herd size, which conditions their future herd size relative to the bifurcated threshold.

Holding risk preferences and basis risk parameters constant, we will now show that the dynamic welfare effect of this insurance contract, represented by $\Delta \eta_i^c$, varies with initial herd sizes relative to the critical threshold. In particular, four distinct cohorts emerge.

1. For the first cohort, IBLI cannot alter their herd dynamics. Their beginning herd size is too far beneath the critical herd size threshold to grow past $H^*$ by the end of the season since even in a good season and without insurance $(\eta_L + \eta_G)H_{it} < H^*$. Thus IBLI only provides typical insurance in reducing the probability of herd loss during a bad season, while the premium payment speeds up herd decumulation during good seasons. By (6), household’s IBLI valuation is the same as that in the standard insurance case without bifurcated asset dynamics:

\[
\Delta \eta_i^c = \left(P \cdot (\eta_L + \eta_G - \rho)_{1-R} + (1-P)(\eta_L + \eta_B + \pi - \rho)_{1-R}\right)^{R-1} \tag{12}
\]

So

\[
\Delta \eta_i^c = \left(P \cdot (\eta_L + \eta_G - \rho)_{1-R} + (1-P)(\eta_L + \eta_B + \pi - \rho)_{1-R}\right)^{R-1} \tag{12}
\]

For this cohort, the value of IBLI depends on the extent to which IBLI imperfectly compensates for the insured’s losses and household-specific risk preferences. However, since households in this cohort converge to the low-level equilibrium with or without insurance, IBLI offers them relatively little in the way of economic relief.

2. The second cohort consists of pastoralists expecting to grow their herds. Beginning herd sizes are modestly above $H^*$ and grow if the season is good and when they do not pay the insurance premium. However, paying the insurance premium drops them beneath $H^*$ so that $H^* < (\eta_L + \eta_G)H_{it} < H^* + \rho_{it}H_{it}$ in a good season. Because IBLI shifts down their herd growth trajectory, the additional risk premium growth rate is
effectively taxed by \( \left( \frac{1 - \delta \eta_{L}^{r_{L}}}{1 - \delta \eta_{H}^{r_{H}}} \right) > 1 \), as is evident from the certainty equivalent growth rate:

\[
\Delta \eta_{il}^{c2} = \left( P \cdot (\eta_{H} + \eta_{G} - \rho_{H})^{1-r_{L}} + (1 - P)(\eta_{H} + \eta_{B} + \pi_{H} - \rho_{H})^{1-r_{H}} \right)^{R^{-1}} \\
- \left( \frac{1 - \delta \eta_{L}^{r_{L}}}{1 - \delta \eta_{H}^{r_{H}}} \right) \cdot \left( P \cdot (\eta_{H} + \eta_{G})^{1-r_{L}} + (1 - P)(\eta_{H} + \eta_{B})^{1-r_{H}} \right)^{R^{-1}}.
\]

The value of IBLI is therefore lower than it would be in the absence of the bifurcated herd dynamics, holding risk preference and basis risk determinants constant.

(3) The third cohort consists of pastoralists with beginning herd sizes slightly above but still vulnerable to the risk of falling below \( H^* \). IBLI protects this cohort from falling below \( H^* \) while their herd size remains above \( H^* \) after paying the insurance premium, \( (\eta_{H} + \eta_{G})H_{it} \geq H^* + \rho_{H}H_{it} \). For them \( H^* - (\pi_{H} - \rho_{H})H_{it} < (\eta_{L} + \eta_{B})H_{it} < H^* \).

Since IBLI preserves their herd growth trajectory, IBLI increases their insurance valuation relative to the case without bifurcated asset dynamics by the factor \( \left( \frac{1 - \delta \eta_{H}^{r_{H}}}{1 - \delta \eta_{L}^{r_{L}}} \right) < 1 \). For this reason, the dynamic welfare impact of IBLI for this cohort is

\[
\Delta \eta_{il}^{c3} = \left( P \cdot (\eta_{H} + \eta_{G} - \rho_{H})^{1-r_{L}} + (1 - P)(\eta_{H} + \eta_{B} + \pi_{H} - \rho_{H})^{1-r_{H}} \right)^{R^{-1}} \\
- \left( P \cdot (\eta_{H} + \eta_{G})^{1-r_{L}} + \left( \frac{1 - \delta \eta_{L}^{r_{L}}}{1 - \delta \eta_{H}^{r_{H}}} \right) \cdot (1 - P) \cdot (\eta_{H} + \eta_{B})^{1-r_{H}} \right)^{R^{-1}}.
\]

(4) The last cohort consists of pastoralists with herd sizes so large that even without insurance they are not expected to fall below the critical herd threshold after covariate shocks; \( (\eta_{H} + \eta_{B})H_{it} \geq H^* \). Thus IBLI would not alter their herd dynamics, just like the first cohort (with the smallest herds). But because these larger herd sizes have higher expected net herd growth, \( \eta_{il} \), their valuation of IBLI is significantly more than those in the first cohort according to

\[
\Delta \eta_{il}^{c4} = \left( P \cdot (\eta_{H} + \eta_{G} - \rho_{H})^{1-r_{L}} + (1 - P)(\eta_{H} + \eta_{B} + \pi_{H} - \rho_{H})^{1-r_{H}} \right)^{R^{-1}} \\
- \left( P \cdot (\eta_{H} + \eta_{G})^{1-r_{L}} + (1 - P) \cdot (\eta_{H} + \eta_{B})^{1-r_{H}} \right)^{R^{-1}}.
\]
Overall, cohorts three and four – the wealthier segments of this at risk population – represent the main source of demand for IBLI in this setting. The expected threshold-based performance of IBLI in the presence of bifurcated wealth dynamics mirrors the patterns found in Lybbert and Barrett (forthcoming) in a different poverty trap model that does not consider insurance options.

5. Empirical Estimation and Simulation

This section estimates the nonlinear herd growth function and the probability distributions of the key IBLI performance parameters defined in the prior section. Specifically, the non-linear net herd growth function in (3) is estimated separately for the non-mortality and the mortality components. Estimations of the mortality component thus allows us to precisely estimate the key basis risk parameters directly from the well-observed correlations between individual households’ livestock mortality and the location-specific predicted herd loss index that triggers IBLI payout. These estimations then allow us to simulate households’ herd dynamics and so the value of IBLI using the framework defined in the previous section. Steps we took in the estimations are as follows.

First, we estimate non-mortality component – comprising of herd reproduction and net offtakes – of the seasonal livestock growth function in (3) using a ground trusting subsistence consumption of 0.5 TLU per household per season. We pool four seasons of herd dynamics data from 2000-2002 and two seasons from 2007-2008 under the maintained hypothesis that the expected herd growth function is stable across 2000-2008. Kernel-weighted local polynomial regression \(^{10}\) is used to estimate two nonparametric relationships between the non-mortality herd growth rates \(^{11}\) and household beginning TLU herd size conditional on whether the observed season is observed with good or bad vegetation conditions, as defined by observed pattern of seasonal NDVI data according to Chantarat et al. (2009a). The two estimated non-mortality growth functions conditional on the vegetation condition will then be used in the simulation of herd dynamics. Appendix 1 provides more detail and plots of these two estimated functions.

Second, we then estimate mortality component in (3). Specifically, we estimate the relationship between household-specific herd mortality rates and the location-average predicted mortality index described in (8) with a working assumption of variations of coefficients across households.\(^{12}\) Given the limited temporal availability of each household-specific data and our simulation purpose, our further working assumption is that the coefficient vectors \((\mu_{ij}, \beta_{ij})\) of different households are drawn from a multivariate probability distribution with a fixed mean and covariate matrix. Thus a

---

\(^{10}\) Epanechnikov kernel function is used and the optimal bandwidth is chosen according to Silverman’s Rule of Thumb.

\(^{11}\) Growth rates were constructed using observations on births, purchases, borrowing and lending of animals, exchanges, sales, slaughters and transfers.

\(^{12}\) Estimation of models of beta-representation (e.g., the CAPM model in financial econometrics) generally rely on the seemingly unrelated regressions model for sector-specific equations, which allows for unrestricted error structures (e.g., due to potentially cross-sectional correlations). In our case, we do not have enough longitudinal observations of individual households to apply that model.
random coefficient model is used and estimated using maximum likelihood of pooled data from four seasons of household-specific mortality rates across the four 2000-2 study locations. Our estimated model significantly rejects the null hypothesis of parameter homogeneity with chi-square (2) = 24.25.

Of course there may still be other covariate-but-unpredicted components, in addition to the idiosyncratic component, in the model’s disturbances, which can potentially result in cross-sectional correlation. In an attempt to disaggregate these two components in the disturbances, the predicted seasonal household-specific residual ε̂ilt is projected onto its location-specific mean each season  over ε̂ilt.13 So the model we estimate can be summarized as

\[
\begin{align*}
\tilde{M}_{ilt}(ndvi_{il}, \epsilon_{ilt}) &= \mu_{ilt} + \beta^{\epsilon}_{ilt} (\tilde{M}(ndvi_{il}) - \mu_i) + \epsilon_{ilt} \\
\epsilon_{ilt} &= \beta^{\epsilon}_{ilt} \bar{\epsilon}_{ilt} + e_{ilt}
\end{align*}
\]

where \( \beta^{\epsilon}_{ilt} \) represents the covariate component in the unpredicted mortality loss with degree of co-variation measured by \( \beta^{\epsilon} \), and \( e_{ilt} \) represents household’s idiosyncratic mortality loss with \( 0 = E(e_{ilt}) \), \( 0 = E(e_{ilt}e_{ilt}') \) if \( i \neq j \), and \( Var(e_{ilt}) = \sigma^2 I \). The estimation results, which allow us to estimate household’s basis-risk-determining parameters14 in \( \{\mu_{ilt}, \beta_{ilt}, \beta^{\epsilon}_{ilt}, e_{ilt}\} \), and are reported in Appendix 2.

We show in Figure 3 the distributions of estimated household betas, as well as the unpredicted component of mortality losses, \( \epsilon_{ilt} \) for these four locations.15 Overall, the beta distribution centered around 0.8 with considerable variation,16 ranging from -0.35 to 2 with a standard deviation of 0.5. The distribution of the mean-zero unpredicted component of mortality losses also exhibits high variation, ranging from -0.42 to 0.44 with a standard deviation of 0.12. This dispersion indicates considerable basis risk in IBLI in spite of the product’s very strong out-of-sample performance (Chantarat et al. 2009a), and the potential for significant, predictable variation in performance across households.

13 The intercept for this model is zero by construction.
14 The estimated results of household-specific mortality loss that cannot be explained by the area average predicted mortality index, \( \epsilon_{ilt} \), are also reported though simulations will now be based on the disaggregated parameters \( \beta^{\epsilon}_{ilt}, e_{ilt} \).
15 Though our estimations and simulations from this point on were location-specific, we report overall results. Some location-specific results are reported in the Appendices; the rest can be requested from the authors.
16 Because the first equation in (16) implies the estimated household beta only with respect to the hedgable mortality index, this does not have to be centered at one, unlike the estimated household beta with respect to area-average losses – such as is commonly used in agricultural finance literature for measuring basis risk of area yield insurance (Carter et al. 2007; Miranda 1991). In contrast, the estimated \( \beta^{\epsilon}_{ilt} \) is centered at one by construction.
Lastly, we then estimate parametrically the best fit joint distributions, by location, of the estimated household-specific characteristics including household-specific starting herd size\(^{17}\) \(\{\mu_{it}, \beta_{it}^\varepsilon, \beta_{it}^\delta, e_{it}, H_{it}\}\) using the @Risk program, which allows us to specify a correlation matrix that captures pairwise relationships structure between these variables, and the upper and lower limits of the distributions. The best-fit distributions were then chosen based on the \(\chi^2\) goodness of fit criterion. The estimation results are reported in Appendix 2.

We then use results of the estimations described above to simulate 54-season herd dynamics of 500 representative households in each of the 4 studied locations. The simulation proceeds in the following 6 steps.

1. For each location, we randomly draw 500 combinations of household-specific basis risk parameters and initial herd size \(\{\mu_{it}, \beta_{it}^\varepsilon, \beta_{it}^\delta, H_{it}\}\) from the joint distributions – each of which represents a simulated representative household.

2. For each location, we acquire 54 seasons of historical NDVI data, which then allow us to construct 54 seasons of area average predicted mortality index \(\hat{\mathcal{M}}(\text{ndvi}_t)\) based on the established predictive relationship in Chantarat et al. (2009a).

3. For each location, as also randomly draw 54 seasons of location-averaged unpredicted mortality losses, \(\tilde{e}_t\), from the values estimated according to (16).

4. For each simulated household, we then randomly draw 54 seasons of idiosyncratic components of mortality loss, \(e_{it}\), from the location-specific distribution.\(^{18}\)

5. The 54 seasons of simulated household-specific and location-specific parameters from 1-4 then allow us to construct 54 seasons of household-specific livestock mortality rates for all of the simulated households.

6. The simulated household-specific beginning herd, 54 seasons of household-specific livestock mortality rates and 54 seasons of location-specific NDVI data then allow us to recursively estimate each of the 54 seasons of the non-mortality herd growth rates and so the resulting herd dynamics for all of the simulated households.

Figure 4 presents the overall cumulative distributions of baseline household herds (i.e., without insurance) during various years for these four locations. More than 50% of herds collapse toward destitution over time in Dirib Gombo, compared to less than 10% in North Horr, reflecting the relatively low beginning herd sizes and high seasonal mortality experience in Dirib Gombo relative to other locations. The bifurcated livestock growth in the simulated herd dynamics can be shown by simply estimating the autoregression in (4) for 10-season (5-year) lags. Figure 5 plots the results, which clearly display a critical herd size threshold around 15 TLU.

\(^{17}\) The overall average herd sizes observed from 2000-2002 and 2007-2008 are used as representatives of the beginning herd sizes in the four locations.

\(^{18}\) We use the location-specific distribution of \(e_{it}\) since we do not have enough individual data to simulate the individual-specific distributions.
To better understand how basis risk and initial herd sizes influence IBLI’s impact on herd dynamics, we also simulate 54-season herd dynamics for 15 stylized pastoralist households with key characteristics, e.g., five different beginning TLU herd sizes \( \{5,10,15,20,30\} \) and three levels of beta coefficients \( \{0.5,1,1.5\} \) for each initial herd size. Each is assumed to have a long-term mortality rate that resembles the location-specific long-term mean predicted mortality index, and a location-specific uncovered risk component.

We are now ready to analyze the effectiveness of various IBLI contract based on the change in certainty equivalent herd growth, \( \Delta \eta^C = \eta(ndvi_{it}, \mu_{it}, \beta_{it}, e_{it}, R_i, H_{it}) \), of the herd dynamics with and without IBLI. There are three principles that we follow.

First, we consider five IBLI contracts with five strike levels of five percent increments from 10-30%. Households are assumed to insure their entire herd. For each contract, we simulate the resulting insured herd dynamics based on (7) using the location-specific seasonal predicted mortality index \( \hat{M}(ndvi_{it}) \) constructed earlier and the location-specific premium rate shown in Table 2.

Second, instead of just concentrating on the 54 historical seasons, IBLI contracts are evaluated based on 54 pseudo sets of 54 consecutive seasons constructed from the existing vegetation data letting each observation serve as an initial period once in a revolving 54-season sequence with the working assumption that these 54 seasons repeat themselves in sequence.\(^{19}\) This allows us to evaluate performance of IBLI taking into account different possible initial realizations of stochastic range conditions.

Third, as we compute the value of insurance based on the expected utility approach, the certainty equivalent herd growth depends on household discount rates and risk preferences. For simplicity, we assume no discounting, \( \delta = 1 \). We calibrate household-specific CRRA parameters based on a simple experimental lottery game run among the households in June-July 2008. Our risk elicitation game follows the simple method used in Binswanger (1980, 1981); Eckel and Grossman (2002); Barr (2003) and Dave et al. (2007). Households were first given 100 Ksh for participating. Then we introduced five lotteries, which vary by risk and expected return. Respondents were invited to use their 100 Ksh to play one of the five lotteries for a real prize, if they wished. If they decided to pay 100 Ksh to play, they were then asked to choose their most preferred lottery to play. A fair coin was then tossed to determine their prize. Six categories of risk aversion associated with six (geometric mean) coefficients of relative risk aversion,\( \{0, 0.1, 0.3, 0.4, 0.7, 1\} \), were derived based on households’ choices (Chantarat et al. 2009c). Appendix 4 summarizes the results of this risk preference elicitation experiment. For each location, we then randomly assign each simulated household with one of the six CRRA parameters based on the observed wealth strata specific distributions of CRRA.

\(^{19}\) This is a harmless assumption. In essence, the typical burn rate approach to weather insurance evaluation assumes that one year is statistically independent of another and that the universe of possibilities is contained within the historical timeframe represented by the data. Thus in probability the likelihood of 54 seasons repeating in sequence is the same as any other sequence of 54 non-repeating seasons.
6. The Effectiveness of IBLI for Managing Livestock Asset Risk

Figure 6 depicts some key patterns of insured herd dynamics, using Kargi and $\beta = 1$ as an example. Panels (a) to (e) each reflect the cumulative distributions of uninsured and insured herd sizes for a single household over a set of 54 simulated seasons.

Panel (a) shows that IBLI does little for pastoralists with a low beginning herd size (e.g., 5 TLU). IBLI cannot prevent these households from falling into destitution given how far they are beneath the critical herd growth threshold ($\sim 15$ TLU). Indeed, paying an insurance premium each season without offsetting indemnities slightly accelerates herd collapse.20

Varying patterns of IBLI performance emerge for pastoralists with herd sizes around the critical herd threshold, i.e., for those whose herd dynamics are very sensitive to shocks. Panel (b) represents a pastoralist with an initial herd size of 15 TLU immediately at or slightly below the critical threshold. This pastoralist was hit by large covariate shocks that so disrupted his asset accumulation that he ended on a decumulating growth path without insurance. But with IBLI imperfectly compensating for the losses, decumulation was averted, and the result was a stabilized growth trajectory. Because IBLI changes his herd dynamics by insuring against catastrophic collapse, the certainty equivalent herd growth associated with IBLI should be relatively high due to the added effect of the bifurcated herd dynamics in the system.

Panel (c) presents the opposite case, in which a pastoralist with the same initial herd size of 15 TLU could slowly climb onto the herd growth trajectory during good vegetative seasons if he did not pay an IBLI premium. If his luck holds, he could escape the poverty trap without IBLI; the premium payments in this case actually retard progress. The difference between panels (b) and (c) purely reflect the ex post effects due to random draws of seasonal condition and reflect the great value of insurance when it proves to have been needed, and also the adverse effects on those who enjoyed a streak of good luck.

Panel (d) presents the case of a pastoralist with 20 TLU, who would be vulnerable to shocks that could knock him onto the decumulation trajectory in the absence of effective insurance. Indeed, we see that for vulnerable households just above the critical herd size threshold, well-designed IBLI can effectively move them away from the poverty trap, substantially lessening the probability of herd size collapse. This is the population that benefits most, in expectation, from IBLI.

Panel (e) depicts the common pattern of IBLI performance for pastoralists with large initial herd sizes – e.g., 30 TLU – who face little immediate danger of falling into destitution. IBLI contracts provide typical insurance, reducing the probability of herd losses, while seasonal premium payments also reduce the chance of reaching extremely

---

20 Our model assumes away possible indirect benefits of IBLI, such as its potential to crowd in finance for ancillary investment and growth. If IBLI crowds in credit access, it may alter the growth trajectory and the critical herd size threshold, opening up the possibility that IBLI benefits the least well-off pastoralists as well. Our data do not permit credible parameterization of such shifts, so we abstract from them in this analysis.
large herd sizes. This simply reflects the second-order stochastic dominance of the insured herd sizes relative to the uninsured.

The ex ante wealth impacts on IBLI performance shown in Figure 6, however, holds constant other household- and location-specific characteristics that determine a household’s basis risk exposure associated with IBLI.21 Holding other things equal, pastoralists with low (high) beta will tend to over (under) insure their herd losses with IBLI, and so they end up paying higher (lower) prices for IBLI that offer unnecessary (insufficient) compensation for their losses, on average. IBLI performance should vary based on the location-specific distributions of uncovered asset risk and the distributions of covariate shocks. On average, IBLI performance will be higher among households with lower dispersion of uncovered risk, i.e., less basis risk. In addition, IBLI performance is also expected to be higher among households in the locations with a higher probability of insurable covariate losses, i.e., greater risk exposure covered by insurance.

We now consider the performance of actuarially fair IBLI contracts conditional on contract specifications and household characteristics. Table 3 reports the change in certainty equivalent herd growth rate (also referred to as the positive risk premium growth rate) associated with IBLI for 15 stylized households (with individual mean mortality fixed at the location-averaged mean predicted mortality index) in each of the four locations.22 Various interesting results emerge.

First, we observe that IBLI performance varies with beginning herd sizes, confirming the patterns shown in Figure 6. IBLI gains are negligible for pastoralists with the lowest herd sizes (5 TLU) and highest for those with the herd sizes around the critical herd threshold (e.g., 15-20 TLU). IBLI does not seem well suited for the poorest herders, whose low endowments leave them trapped by the underlying dynamics of the system, not by uninsured risk exposure. By contrast, those with marginally viable herd sizes are especially susceptible to shocks thus insurance is potentially of considerable benefit to them.

Second, IBLI performance tends to improve as beta increases, holding other things equal. This implies that over-insuring tends to have far larger adverse impact on herd dynamics than does underinsuring. Indeed, IBLI typically benefits most those with beta=1.5 rather than those whose herd sizes tend to move one-for-one with local averages. Households with greater-than-average risk exposure (e.g., beta>1) find IBLI especially valuable, despite only-partial coverage from IBLI.

Finally, these simulations suggest that the IBLI contract with a 10% strike level outperforms other contracts, on average, even though the 10% strike contract is more costly than the others. The greater protection apparently is worth it given the risk of falling beneath the critical herd size threshold. This effect is most pronounced for those

---

21 And so it is possible for some pastoralists with as high as 40 TLU to still be vulnerable to shock, and so can benefit greatly from IBLI in preserving their growth trajectory.

22 For simplicity, Table 3 only reports certainty equivalent results calculated with respect to a CRRA value of 0.7. Results for other degrees of CRRA are similar and are available by request. Location-specific results are available by request.
with initial herd sizes just above the threshold (at 20 TLU), whose vulnerability to shocks is best addressed with a low strike insurance contract.

Having observed how variations in household-specific characteristics could affect individual-level IBLI performance, we now explore how the observed location-specific distributions of those characteristics affect IBLI performance at a more aggregate scale. Table 4 first reports the overall performance of actuarially fair IBLI contracts among 2000 simulated pastoralists across the four locations.

The 10% strike contract appears to have the highest performance holding other things equal. On average, actuarially fair IBLI contracts with a 10% strike level result in a 17% increase in the long-term mean herd size, and a reduction in downside risk of 12%.23 On average, certainty equivalent herd growth increases only modestly with increasing risk aversion.

In general, effective demand for IBLI (e.g., positive risk premium herd growth rate) exists in all locations for IBLI contracts with less than a 30% strike, with the highest demand for the 10% strike contract. But not everyone benefits. Figure 7 presents the cumulative distributions of the improvement in certainty equivalent growth rates with respect to three different IBLI contracts in these four locations. At least half the households benefit from an IBLI contract with a 10% strike (slightly lower proportions for other strike levels) with the positive risk premium growth rates associated with the contract ranging up to almost 100%. The distribution of valuations for the 10% contract clearly dominates that of the other contracts in these locations.

### 7. Willingness to Pay and Potential Demand for IBLI

The preceding analysis offers a glimpse into prospective demand patterns for IBLI. So far, we have explored the performance of IBLI contracts sold at actuarially fair premium rates. But an insurer needs to add a commercial loading. This will change the impact of IBLI on herd dynamics by changing the premium paid for insurance. We can use this same simulation model to estimate demand for IBLI by searching for the \( \rho^\alpha \) that drives the risk premium growth rate to zero. In this section, we explore demand for the 10% strike IBLI contract previously shown to have the greatest expected benefit for most pastoralists in the region.

We first estimate the maximum willingness to pay (WTP) for IBLI of each simulated pastoralist by searching for the maximum premium loading \( (\alpha) \) according to (2) that still yields a non-negative risk premium growth rate. The expected maximum willingness to pay conditional on household initial herd size is then estimated

---

23 These two measures are used widely in the mean-variance evaluation approach of agricultural insurance. Downside risk reduction is measured by semi-variance reduction of the insured herd dynamics with IBLI relative to the uninsured herd. Specifically, semi-variance of the insured herd dynamics over a set of consecutive seasons \( t, \ldots, T \), denoted by \( \{ \tilde{H}^I_{t, t+1} \} \), relative to some threshold, for example, household’s long-term mean herd size \( \tilde{H}_u \), can be well written as \( \text{SV}_{\tilde{H}_u} (\tilde{H}^I_{t, t+1}) = EMa(x(\tilde{H}^I_{t, t+1} - \tilde{H}_u, 0)^2) \).
nonparametrically across 2000 simulated pastoralists. The average herd-conditional WTP is shown in Figure 8, plotted against the observed herd size distribution.

WTP for IBLI above the actuarially fair rate is only attained at herd sizes of at least 15 TLU, just around the threshold at which herd dynamics bifurcate. Since most households’ herds fall below the threshold level, this implies limited potential demand for even actuarially fairly priced IBLI. Expected WTP increases at an increasing rate for those with herd sizes between 15-20 TLU and then continues to increase significantly toward its peak at an average 18% loading at the herd sizes around 40 TLU – just below the high-level herd size equilibrium – after which there is no statistically significant change in WTP as herd size increases. The clear implication is that WTP may not be high enough for a commercially viable IBLI absent subsidies.

Based on these estimated distributions of households’ WTP for IBLI in each location, we now study potential aggregate demand. Specifically, we construct a district-level aggregate demand curve for Marsabit District as follows. Assuming that the 2000 simulated households in the four study locations are randomly drawn from the total population of 27,780 households in 28 locations in Marsabit District, we treat each simulated household as representing approximately 14 households in the District population. We then order the WTP across the population and plot the premium loadings (a) against the cumulative herd sizes of the population whose WTP would support commercial demand at that loading level.

Figure 9 displays the estimated aggregate demand curve for IBLI in Marsabit District and disaggregates it for each of three herd size groups: (i) the low herd group (with < 10 TLU) representing the 26% of the population that currently finds itself on a herd decumulation trajectory into a stockless poverty trap, (ii) vulnerable pastoralists (with 10-30 TLU) representing the 47% of the population who risk collapsing into the poverty trap with the next uninsured shock to their herd size, and (iii) the better off pastoralists (with > 30 TLU) who represent the 27% of population that control most of the District’s livestock herd and who, in the absence of an unusually severe shock or series of such shocks, should be securely on a growth path.

Aggregate demand for IBLI seems very price elastic with reduction in quantity demanded by 55% as the fair premium rate is loaded by 20%, and a further 26% reduction with an additional 20% premium loading. If the commercially viable IBLI contract rate is set at a 20% loading, these highly elastic aggregate demand patterns show potential aggregate demand of approximately 210,000 TLU in Marsabit District alone. These patterns highlight several points. First, large herd owners will be the key drivers of a commercially sustainable IBLI product. Second, the apparent price elasticity of demand in these locations implies that a small premium reduction (e.g., through subsidization) can potentially induce large increases in quantity demanded. For example, as Figure 9 shows, a decrease in premium loading from 40% to 20% could potentially induce more than a doubling of aggregate demand. Third, while IBLI appears most valuable for the most vulnerable pastoralists (those with herd sizes around 10-30 TLU) as it could protect their herd dynamics from catastrophic shock, most of their WTP lies well below the

---

commercially loaded IBLI premium (i.e., at least a 20% loading). This, as we showed in Figure 6 panel (c), is due to the possibility that high premium payments will impede herd accumulation across the herd growth threshold.

Premium subsidization may therefore be important if it is socially desirable to stimulate IBLI uptake among vulnerable populations. Might IBLI subsidies provide a cost-effective and productive safety net in broader social protection programs sponsored by governments or donors? That is the final question we explore using these simulation models.

8. Enhancing Productive Safety Nets Using IBLI

In order to investigate whether IBLI subsidies might effectively provide a productive safety net for pastoralists in northern Kenya, we first explore herd and poverty dynamic outcomes (using an asset poverty line of 10 TLU) of these 2000 simulated pastoralists under four different scenarios: (i) without insurance, (ii) with commercially loaded IBLI (assuming a 20% premium), (iii) with an optimally targeted premium subsidization scheme that maximizes asset poverty reduction outcomes, and (iv) with comparable, needs-based subsidization targeted to the poorest households with less than 20 TLU.

The targeted premium subsidization scheme is optimized by searching for the combination of subsidized premium rates targeted to different herd groups – (a) the poorest (<10 TLU), (b) the non-poor likely to fall into poverty in the longer run (10-20 TLU), (c) the vulnerable non-poor (20-30 TLU), (d) the secure pastoralists (30-50 TLU), and (e) the large-scale pastoralists with >50 TLU – that yields the lowest poverty outcomes. The results (details available by request) imply that the optimal premium subsidization scheme would provide IBLI free to group (b) and at the actuarially fair premium rate for the vulnerable non-poor groups (c) and (d), with no subsidization to groups (a) and (e). We compare this with two needs-based schemes: subsidized to the fair rate (a = 0%) and free provision targeted to the less well off pastoralists with herd sizes less than 20 TLU.

In each of these scenarios, the simulated household herd at the end of each season reflects the household’s optimal insurance choice – i.e., insure if (induced) WTP exceeds the (subsidized) premium rate, do not insure otherwise. Therefore, the herd outcomes for the case of strictly commercial IBLI, for example, largely represent the outcomes of the insured herds of the well off pastoralists who demand WTP even at commercial rates and the uninsured herds of the rest of the population. Figure 10 depicts these herd dynamic outcomes in the form of mean household herd size and asset poverty (<10 TLU) headcount measures estimated from the 2000 simulated household over the 54 seasons of available NDVI data, 1982-2008.

The commercially loaded IBLI without subsidization, which only attracts a majority of the well-off pastoralists, has very limited effect on poverty. Average herd sizes under this scenario closely track the no-insurance case, with only modest increases largely among insured, well-off pastoralists partially protected from shocks by IBLI.

By contrast, under the optimal subsidy scheme, mean herd sizes increase more than 80%, relative to the no insurance case, over the course of a quarter century.
Likewise, the asset poverty headcount decreases slightly over time and stabilizes at a level about 10% lower than without insurance. Subsidized IBLI protects many targeted pastoralists herds against collapse beneath the critical growth threshold.

The most distributionally progressive, strictly need-based schemes achieve less than half of these optimal outcomes. While they follow similar (herd size increasing and poverty decreasing) patterns, we still observe increasing poverty headcounts even with free IBLI for the poorest. This simply reflects the fact that IBLI provides little benefit for pastoralists with low herd sizes or with high basis risk exposure. Perhaps counter-intuitively, allocating scarce resources to subsidize the vulnerable non-poor may do more to keep long-term poverty headcount rates down than allocating the same resources to the poorest.

In this simple simulation, the average cost of the optimal targeted subsidization scheme, which reaches 20%-50% of the population over 54 historical seasons, is roughly $50 per beneficiary per six-month season.\(^{25}\) This implies a $20 per capita cost per one percent reduction in the poverty headcount rate, in contrast to $38 for the needs-based scheme. An effective safety net can be both cheaper and more effective in stemming long-run poverty than traditional transfer programs (Barrett et al. 2008).

9. Conclusions

Covariate livestock mortality is a key source of vulnerability among east African pastoralists and often drives households into extreme persistent poverty. In the presence of poverty traps resulting from well-documented nonlinear herd growth dynamics in the region, effective risk management becomes potentially important as a means of reducing long-term poverty rates. This paper offers novel dynamic estimates of the welfare effects of a new index-based livestock insurance (IBLI) product developed to address precisely this problem; IBLI is scheduled for pilot sales in early 2010 in northern Kenya.

Our analysis adds to the current literature because of our focus on asset risk – rather than income risk – and the existence of bifurcated asset dynamics in the northern Kenyan pastoral system. These two characteristics require important innovations in ex ante impact assessment of insurance. We develop a dynamic simulation model and a modified expected utility-based evaluation criterion in order to take into account the potential dynamic impact of IBLI. We use household-level parameter estimates including household-specific risk preferences elicited from field experiments as well as basis risk parameters estimated from panel data from the region to explore a) key patterns of variation in IBLI performance, b) patterns of willingness to pay, and c) the aggregate demand for IBLI.

We find that household initial herd size – i.e., ex ante wealth – is the key determinant of IBLI performance, more so than household risk preferences or basis risk exposure. IBLI works least well for the poorest, whose meager endowments effectively condemn them to herd collapse given prevailing herd dynamics. By contrast, IBLI is

\(^{25}\) One TLU is valued at 12,000 Ksh, approximately $160 based on October 2009 exchange rates (75.05Ksh/US$).
most valuable for the vulnerable non-poor, for whom insurance can stem collapses onto a trajectory of herd decumulation following predictable shocks.

We find that a 10% strike contract consistently outperforms higher strike level contracts. District-level aggregate demand appears highly price elastic with potentially limited demand for contracts with commercially viable premium loadings. Because willingness to pay is especially price sensitive among the most vulnerable pastoralists (i.e. those not currently caught in a poverty trap, but on the verge of falling into one) for whom the product is potentially most beneficial, subsidization of asset insurance as a safety net intervention may prove worthwhile. Simple simulations find that relatively inexpensive, partial subsidization targeted to households with herd sizes in specific ranges can significantly increase average wealth and decrease poverty, at a rate of just $20 per capita per one percent reduction in the poverty headcount rate.

Appendix 1: Non-mortality Component of Herd Growth Function

Chantarat et al. (2009a) defines good seasons as those with positive cumulative deviation of NDVI observed at the end of the season and bad seasons as those with non-positive cumulative deviation of NDVI. Below we plot the two nonparametrically estimated non-mortality growth functions conditional on vegetation conditions, which we use as the basis for the simulations. The conditional herd mortality rates are also plotted here to illustrate that during the good seasons, more households enjoy positive net growth rates (i.e., mortality rate below non-mortality growth rate), while those above the critical herd size threshold of 12-20 animals maintain just slightly above zero growth during the bad seasons. Santos and Barrett (2007) report similar findings.

Appendix 3: Summary of Baseline Simulation Results
Appendix 4: Summary of Risk Preference Elicitation

The left panel of Table A4 presents the gambling choice set with 50% probability of yielding either a low or high payoff. The first gamble choice reflects the situation if the pastoralist chooses instead not to play the game, i.e., to keep the certain 100 Ksh compensation. For gamble choices 2-5, expected returns\(^{26}\) increase by 5 Ksh while the risk (standard deviation) increases by 2 Ksh. Gamble choice 6, however, involves only an increase in risk with the same expected return as gamble choice. Extreme risk averse pastoralists would sacrifice expected return to avoid risk and choose the sure bet (Gamble 1). A moderately risk averse household would choose an intermediate bet (Gamble 2-4). Risk neutral pastoralist would choose gamble choice 5 or 6, which have the highest expected returns. A risk seeker would choose gamble 6 in search of a higher potential payoff. This experiment was designed to be as simple as possible, while retaining reasonable ranges of risk choices.

Though this simple elicitation method produces coarse categorical estimates of risk aversion, they work well compared to more complicated methods, especially among subjects with little or no literacy (Dave et al. 2007; Dohmen et al. 2007; Anderson and Mellor 2008). We estimate the range of coefficients of relative risk aversion implied by each possible choice of gambles under the assumption of constant relative risk aversion (CRRA) according to:

\[
E(U(P)) = \sum_k \pi_k U(P_k) = \sum_k \pi_k \left( \frac{P_k^{1-R}}{1-R} \right), \quad U'(P) > 0, \quad 0 \leq \pi \leq 1 \text{ and } k=1,2.
\]

\(\pi\) represents probability of each possible payoff P and \(R\) is the CRRA coefficient. In each case, the upper (lower) bound of \(R\) can be calculated as the value of \(R\) that generates same utility level for the payoffs associated with the preferred gamble and the

\(^{26}\) For gamble 2-5, the sample numbers are linearly related to the properties of the gamble in term of expected return and variance. The relationship between expected return and variance can be summarized by \(E(R) = 100 + 0.2SD\). The gamble number (G) can be written as \(G = 0.2E(R) - 19\). The gamble number is therefore a reasonable parametric summary index of risk preference.
less (more) risky adjacent. A value of $R \in (0,1)$ reflects a risk averse household.\(^{27}\) The value $R = 0$ is associated with a risk neutral household, while $R < 0$ indicates a risk seeker. Following Binswanger (1980), we assign a mean CRRA measures to each of the ranges using the geometric mean of the two end points.\(^{28}\) In the case of gamble 6, a value of zero is given to the CRRA measure to represent a class of risk neutral or risk seeker. The value of one is then assigned to the case of gamble 1 to represent the extremely risk averse class. We then assign each household to one of the six risk aversion classifications (extreme, severe, intermediate, moderate, low/neutral and neutral/risk seeker).

</tbody>
</table>

* Without assumption of $R \leq 1$, the actual value of $R$ is 1.67.

Below are plots the cumulative distributions of CRRA associated with each of the three livestock wealth strata used in the 2008 survey.

\(^{27}\) In our setting, we truncated R at the maximum value of 1 as we only consider CRRA class utility function that is increasing. Value of R greater than 1 will yield negative value of utility.

\(^{28}\) For the case of gamble 5 with one of the end point at zero, arithmetic mean was chosen in this case.
